ABSTRACT

Background: Environmental determinants of appendicitis are poorly understood. Past work suggests that air pollution may increase the risk of appendicitis.

Objectives: We investigated whether ambient ground-level ozone concentrations were associated with appendicitis and whether these associations varied between perforated and nonperforated appendicitis.

Methods: This time-stratified case-crossover study was based on 35,811 individuals hospitalized with appendicitis from 2004-2008 in 12 Canadian cities. Data from a national network of fixed-site monitors were used to calculate daily maximum ozone concentrations for each city. Conditional logistic regression was used to estimate city-specific odds ratios (OR) relative to an interquartile range (IQR) increase in ozone adjusted for temperature and relative humidity. A random effects meta-analysis was used to derive a pooled risk estimate. Stratified analyses were used to estimate associations separately for perforated and nonperforated appendicitis.

Results: Overall, a 16 ppb increase in the 7-day cumulative average daily maximum ozone concentration was associated with all appendicitis cases across the 12 cities (pooled OR=1.07; 95% CI: 1.02, 1.13). The association was stronger among patients presenting with perforated appendicitis for the 7-day average (pooled OR=1.22; 95% CI: 1.09, 1.36), when compared to the corresponding estimate for nonperforated appendicitis (7-day average: pooled OR=1.02, 95% CI: 0.95, 1.09). Heterogeneity was not statistically significant across cities for either perforated or nonperforated appendicitis (p>0.20).

Conclusions: Our findings suggest that higher levels of ambient ozone exposure may increase the risk of perforated appendicitis.
INTRODUCTION

The lifetime risk of appendicitis is approximately 1 in 15, and appendectomy for appendicitis is amongst the most frequently performed operations in developed nations (Hardin 1999). Perforated appendicitis has a worse prognosis than nonperforated due to increased risks of sepsis and mortality (Hardin 1999). Perforated appendicitis may result from delayed treatment (Bickell et al. 2006), but others have suggested that it may be a distinct phenotype with diverging pathogenesis from nonperforated appendicitis (Andersson 1999; Livingston et al. 2007; Ruber et al. 2010; Ruber et al. 2006). In the United States, appendicitis-related hospitalizations contribute to approximately $3 billion in hospital charges annually (Davies et al. 2004). Thus, appendicitis is a relatively common disease that imparts a significant burden to patients and to the health care system (Davies et al. 2004).

Despite the health and economic impacts of this disease, the pathogenesis of appendicitis remains largely unknown. Consistent epidemiological features of appendicitis include an elevated risk associated with younger age, male gender, Caucasian race, and during warmer seasons (Addiss et al. 1990; Luckmann and Davis 1991). Additionally, temporal-spatial clustering of appendicitis cases has been reported, which suggests that acute environmental exposures might contribute to the pathogenesis of appendicitis (Andersson et al. 1995).

A decrease in the incidence of appendicitis in developed countries during the latter part of the 20th century (Addiss et al. 1990; Ferris et al. 2010) coincided with the enactment of legislation that led to reductions in the concentrations of several outdoor air pollutants (Chen et al. 2007). This motivated a previous study of short-term changes in air pollution and appendicitis in
Calgary, Alberta, which indicated that the 7-day average concentration of ambient ozone was positively associated with appendicitis (Kaplan et al. 2009). Further, several recent animal studies have shown that air pollution exposure may alter intestinal immunity, increase gut permeability, and influence intestinal microbial composition (Kaplan et al. 2012; Kish et al. 2013; Mutlu et al. 2011). Such effects might predispose certain individuals to develop appendicitis, or might influence the clinical presentation of appendicitis.

To our knowledge, there has been no attempt to replicate our previously reported association between ozone exposure and appendicitis (Kaplan et al. 2009), or to evaluate associations according to appendicitis presentation (i.e. perforated versus nonperforated appendicitis). Therefore, we conducted a multi-city population-based case-crossover study of appendicitis patients to estimate associations between short-term ambient ozone concentrations and appendicitis across multiple Canadian cities. In addition, we examined whether associations varied between perforated and nonperforated appendicitis cases.

**METHODS**

**Study Population**

The Discharge Abstract Database, maintained by the Canadian Institute for Health Information (CIHI), was used to identify individuals hospitalized with appendicitis (Lalonde and Taylor 1997). This database includes all inpatient discharges from nine provinces and two territories (Quebec excluded) (Lalonde and Taylor 1997). Patients hospitalized with appendicitis between January 1, 2004 and December 31, 2008 were identified for the following 12 cities: Vancouver, Calgary, Edmonton, Saskatoon, Regina, Winnipeg, Windsor, London, Hamilton, Toronto, Ottawa, and Halifax. These cities were selected because of their large populations and the
availability of appendicitis data and daily ozone monitoring data collected by Environment Canada for > 80% of the study days. Appendicitis patients living outside city boundaries were identified based on their postal code and excluded from the analysis.

An incident case of appendicitis was identified by a diagnostic code for nonperforated appendicitis (International Classification of Diseases 10th Revision coding ICD-10-CA K35.9) or perforated appendicitis (ICD-10-CA K35.0 and K35.1) and a concurrent procedural code for appendectomy (Canadian Classification of Health Interventions: 1.NV.89.DA and 1.NV.89.LA) (CIHI Website 2013). Individuals coded with unspecified or other appendicitis (e.g. chronic or recurrent appendicitis) were excluded. Sensitivity and positive predictive value of ICD-10-CA coding for appendicitis were 94% and 85%, respectively (Kareemi et al. 2012).

**Air Pollution Exposure Assessment**

Environment Canada’s National Air Pollution Surveillance network monitors ambient ozone levels in over 150 stations in 55 cities across Canada. Automated fixed-site continuous monitoring stations collect hourly mean concentration data that are used to calculate daily maximum ozone concentrations. When there were multiple monitors in a given city, ozone concentrations were averaged into a daily value for the city (Sajani et al. 2010). Additionally, daily mean concentrations of nitrogen dioxide (NO₂) and particulate matter less than 2.5 microns (PM₂.₅) were determined using data from fixed monitoring sites. Data for daily mean temperature and relative humidity were also provided by Environment Canada.

**Study Design**

Associations between ambient ozone concentrations and appendicitis were investigated using a time-stratified case crossover study design (Schwartz 2004). This design is an adaptation of the
case–control study in which cases serve as their own controls (Maclure 1991). For each case of appendicitis, air pollution exposure on the “index” day (i.e. the day of appendicitis admission) is compared to exposure on a series of referent days that occur on the same day of the week during the same month and year as the index day. Because all comparisons are within-individuals, confounding by individual-level risk factors is controlled by the design because these factors are not expected to vary within the one-month time frame that includes the index and referent days (e.g. genetics and obesity) (Schwartz 2004; Levy et al. 2001). Selecting referent intervals close in time to the case event also controls for seasonal patterns in disease occurrence. Although there is variation in the number of referent days that occur after or before the case event, over all appendicitis cases, the numbers of referent days before and after case events are comparable and there is no bias resulting from time trends (Janes et al. 2005; Levy et al. 2001; Schwartz 2004).

**Statistical Analysis**

Associations between ambient ozone concentrations and appendicitis were examined using the one-hour daily maximum ozone concentrations on the same day or on the previous day, and also using the average of one-hour daily maximum ozone concentrations over the 3-, 5-, or 7-days prior to the event day or referent days, not including the event or referent days. The 3-, 5-, and 7-day averages of ozone were previously shown to be associated with appendicitis (Kaplan et al. 2009) and were therefore identified *a priori* as the primary exposures of interest. Conditional logistic regression was used to estimate the odds of appendicitis in relation to an interquartile range (IQR) increase in the daily maximum ozone concentration adjusted for mean temperature and relative humidity on the event or referent day. The IQR (16 ppb) was based on daily one-hour maximum ozone levels throughout the entire study period (January 1, 2004–December 31,
City-specific odds ratios (OR) and 95% confidence intervals (CI) were pooled using a random effects meta-analysis, which is less prone to bias due to heterogeneity. Heterogeneity in OR estimates across the cities was evaluated using Cochran’s Q statistic and quantified using I².

We evaluated potential confounding by other air pollutants using two-pollutant models adjusted for NO₂ or PM₂.₅ during the same exposure periods as ozone. Stratified analyses were used to estimate associations between ambient ozone exposure and appendicitis according to age (< 20 years, 20 to 39, and ≥40 years), sex, season [spring (March-May), summer (June-August), autumn (September-November), and winter (December-February)], and appendicitis phenotype (perforated versus nonperforated). Stratified models were compared using the Cochrane Q statistic.

We performed several sensitivity analyses. We excluded observations from Halifax to evaluate the impact of missing ozone data (missing for ~20% of days in Halifax compared with <1% of days for the other 11 cities) on the overall pooled risk estimate. We also conducted a sensitivity analysis that included all cases with a diagnostic code for appendicitis (i.e. not restricted to those with also a procedural code). We also conducted analyses with exposure defined based on 24-hour mean ozone concentrations instead of daily 1-hour maximum concentrations, and analyses of associations with an exposure contrast of 10 ppb instead of 16 ppb (the IQR). In addition we estimated associations adjusting for temperature and humidity during the same exposure periods as ozone, instead of adjusting for temperature and humidity on the event or referent days only.

All statistical analyses were conducted in SAS (version 9.2, SAS, Cary, North Carolina). In all instances, a P-value < 0.05 was considered as statistically significant. The study was approved
by the Conjoint Health Research Ethics Board at the University of Calgary who also granted a waiver of consent due to anonymized administrative data. Our study was conducted in accordance with the strengthening of the reporting of observational studies in epidemiology (STROBE) statement (Vandenbroucke et al. 2007).

RESULTS

A total of 35,811 patients were classified as appendicitis based on the presence of both a diagnostic code for appendicitis and a procedural code for appendectomy in the 12 Canadian cities between 2004 and 2008. The median age at diagnosis was 30 years (IQR=19-45 years), 55% were male, and 31% had perforated appendicitis (Table 1). The median daily maximum ozone concentration for the 12 cities was 33.3 ppb (IQR= 16 ppb).

The 7-day average daily maximum ozone concentration was positively associated with appendicitis in the pooled analysis (OR=1.07; 95% CI: 1.02, 1.13) (Table 2), with little evidence of heterogeneity across the cities (P=0.89) (Supplemental Material, Table S1). Exposure was more strongly associated with perforated appendicitis, with ORs increasing as the time period of exposure increased from 3 to 7 days (3-days OR=1.11; 95% CI: 1.01, 1.23, 5-days OR=1.15; 95% CI: 1.04, 1.27, 7-days OR=1.22; 95% CI: 1.09, 1.36) (Table 2). In contrast, ozone exposure was not associated with nonperforated appendicitis (7-day: OR=1.02; 95% CI: 0.95, 1.09) (Table 2). The ORs for perforated cases were significantly different from corresponding ORs for nonperforated cases for all averaging periods (all p<0.05). Forrest plots for city-specific risk estimates of the 7-day average stratified by perforated and nonperforated appendicitis are presented in Figure 1. The OR for the association between the 7-day average of ozone and perforated appendicitis was above 1 for all cities except for Saskatoon (OR=0.63; 95% CI: 0.31,
Heterogeneity was not statistically significant for the 7-day average for nonperforated appendicitis (P=0.48) and perforated appendicitis (P=0.29) (Supplemental Material, Table S1).

The pooled odds ratio for the 7-day average did not vary significantly (all p>0.05) when stratified according to age group, sex, or season (Table 2). Pooled ORs for all appendicitis and perforated appendicitis were comparable to those for the population as a whole when Halifax was excluded (Table 2). Pooled ORs for both outcomes also were similar when adjusted for NO₂ or PM₂.₅ in two-pollutant models. Our findings did not substantially change when adjusted for temperature and humidity during the same exposure period as ozone (instead of temperature and humidity on the index or referent days) (7-day average for perforated appendicitis: OR=1.19; 95% CI: 1.06, 1.35) or when estimated for 24-hour mean ozone concentrations instead of daily 1-hour maximum concentrations (7-day average for perforated appendicitis: OR=1.18; 95% CI: 1.07, 1.30). Consistent with expectations, associations were weaker when estimated for a 10 ppb increase in daily 1-hour maximum ozone (7-day average for perforated appendicitis: OR= 1.13; 95% CI: 1.05, 1.21) instead of an IQR (16 ppb) increase (Supplemental Material, Table S2).

**DISCUSSION**

In this multi-city study, short-term exposure to ambient ozone was associated with an increased number of hospital visits for appendicitis. The findings were robust across a number of sensitivity analyses and consistent with a prior single-city study (Kaplan et al. 2009). Associations with ozone were evident for perforated appendicitis, but not nonperforated appendicitis. We estimated an 11% to 22% increase in perforated appendicitis with every 16 ppb increase in daily 1-hour maximum ozone levels when averaged over the previous 3 to 7 days.
While the pooled relative risk estimates were modest in magnitude, our findings are consistent with previously reported associations between ozone and asthma (Villeneuve et al. 2007). This study of nearly 58,000 asthma visits to emergency departments in Edmonton, Alberta demonstrated that an increase of 24 ppb of the 5-day average of ozone exposure was associated with an 8% increase in asthma exacerbations (Villeneuve et al. 2007). Our pooled estimates for associations with all appendicitis were consistent with a previous single-city study for Calgary, Alberta, one of the cities included in the present analysis (Kaplan et al. 2009). Two previous studies found no association between air pollution and appendicitis (McGowan et al. 2002; Ponka and Virtanen 1996). However, McGowan et al conducted a time series analysis and only studied particulate matter (McGowan et al., 2002), whereas the study from Helsinki analyzed the data using Poisson regression modeling and did not evaluate a multi-day cumulative average of exposure of ozone (Ponka and Virtanen 1996).

We did not observe statistically significant departures from homogeneity across the 12 cities studied. However, ozone concentrations were inversely associated with perforated appendicitis in Saskatoon, in contrast with the other 11 cities. Differences among the cities could reflect differences in the temporal or spatial variability of ozone levels for individual cities. NAPS monitoring stations are generally located in areas with air pollution levels that are expected to be representative of background concentrations in a city. Although averaging measurements from multiple fixed monitoring sites into one daily value for the entire city may misclassify exposures at the individual level (Sajani et al. 2010), this potential biases is likely to be low for ozone because ozone levels are spatially homogeneous across a region (Chen et al. 2007). Missing data may have contributed to variability among cities; however, associations were essentially
unchanged when the city of Halifax, where daily ozone levels were missing for ~20% of the study period, was excluded from the analysis.

Our findings were robust across numerous different approaches to analyzing the data. Although appendicitis is more often diagnosed in young individuals (Addiss et al. 1990; Luckmann and Davis 1991) and in males (Addiss et al. 1990; Luckmann and Davis 1991) neither age nor sex appeared to influence associations between ozone and appendicitis in our study population. Ozone levels are lower in winter months (Chen et al. 2007), when people are also less likely to be exposed to ambient ozone because of increased time spent indoors, thus potentially increasing the likelihood of exposure misclassification. Associations were inconsistent when stratified by season. For example, during the summer, perforated appendicitis was negatively associated with exposure on the same day (OR=0.88; 95% CI: 0.79, 0.99), but positively associated with exposure averaged over the 7 previous days (OR=1.21; 95% CI: 1.02, 1.44). However, season-stratified associations should be interpreted cautiously because the sample sizes were reduced and the differences between seasons were not statistically significant. Finally, although air pollutants are often correlated (Chen et al. 2007), estimates from two-pollutant models adjusted for NO₂ or PM₂.₅ were comparable to adjusted estimates, suggesting that associations between ozone and perforated appendicitis were not confounded by these other air pollutants.

Ozone may selectively influence the pathogenesis of perforated as compared to nonperforated appendicitis. While perforated appendicitis may result from a delay in diagnosing appendicitis (Bickell et al. 2006), emerging evidence suggests that perforated appendicitis also may represent a distinct disease phenotype (Andersson 1999; Ruber et al. 2010). For example, perforated appendicitis may have a divergent immunological pathogenesis (e.g. Th-17 predominant) as compared to nonperforated appendicitis (Ruber et al. 2010; Ruber et al. 2006). Ozone exposure
in humans induced a pro-inflammatory systemic response through stimulation of tumor necrosis factor, IL-6, and IL-8 (Bosson et al. 2007; Paulesu et al. 1991; Srebot et al. 2009; Thompson et al. 2010). Additionally, in an animal study, exposure to air pollutants elevated IL-8 and IL-17 in the small and large bowel and altered the intestinal microflora of mice (Kish et al. 2013). Further, increased intestinal permeability in mice exposed to particulate matter appeared to result from increased inflammation, disruption of tight junctions, and death of epithelial cells (Mutlu et al. 2011). Potential effects of air pollution on pro-inflammatory immune responses and on the host microbiome, could contribute to the development of perforated appendicitis.

Alternatively, the differential association of ozone with perforated versus nonperforated appendicitis may be non-causal. Case definitions of appendicitis were based on ICD coding of an administrative database. A validation study comparing ICD coding of appendicitis against pathology proven appendicitis suggested high sensitivity (>90%), but approximately 15% of cases were false positives (e.g. misclassifying incidental appendectomy of a normal appendix as appendicitis) (Kareemi et al. 2012). Non-differential misclassification error of the disease outcome may bias the risk estimates. Cases coded as perforated appendicitis are less likely to be false-positive or false-negative than cases coded as nonperforated appendicitis (Kareemi et al. 2012). Thus, the association between ozone and perforated appendicitis may represent the relationship between ozone and appendicitis when outcome misclassification is minimized. Additional studies of pathology-proven nonperforated and perforated appendicitis cases are needed to confirm that associations with ozone are specific to perforated appendicitis, rather than overall appendicitis.

Several other limitations should be considered. First, ozone exposure was regionally assigned rather than measured at the patient level. Second, the measurement of ozone levels was
restricted to ambient levels that may not represent indoor exposures. Third, multiple comparisons were performed in stratified analyses and thus, some significant findings may have occurred by chance. Fourth, small sample sizes in some of the cities (e.g. Saskatoon) may have led to spurious associations. Fifth, while each person serves as their own control in a case crossover study design, we cannot rule out residual confounding by time varying factors. Fifth, socioeconomic status may influence the development of perforated as compared to nonperforated appendicitis. Recent studies have reported that socioeconomic status was not associated with the risk of perforated appendicitis in large cohorts in the US and Canada. (Lee et al. 2011; Livingston and Fairlie 2012; To and Langer 2010). In addition, access to health care is less influenced by socioeconomic status because of universal health coverage in Canada. Nonetheless, additional studies are necessary to determine whether the association between ozone and perforated appendicitis is modified by socioeconomic status. Finally, ozone may not be a causal factor, but may instead represent a proxy marker of one or more causal exposures. However, associations between ozone and perforated appendicitis were not appreciably altered by adjustment for NO₂ or PM_{2.5} in two-pollutant models.

**CONCLUSIONS**

We conducted a multi-city study that used a validated case definition and controlled for potential confounders through the case-crossover study design, adjustment for meteorological effects, and the selection of referent intervals using a time-stratified approach. Our findings suggest that short-term ambient ozone exposure increases the risk of perforated appendicitis. Consequently, air pollution may be a contributing factor to the pathogenesis of appendicitis.

</table>

OR – odds ratio; CI – confidence interval; PM<sub>2.5</sub> - particulate matter less than 2.5 microns in diameter

<sup>a</sup>Conditional logistic regression estimated the odds of appendicitis in association with a 16 ppb increase in the daily maximum ozone concentration adjusted for mean temperature and relative humidity on the same day as admission for appendicitis.

<sup>b</sup>Original definition includes a diagnostic code for appendicitis and a procedural code for appendectomy.
Figure Legend

**Figure 1:** Forest Plot for pooled and city-specific odds ratios (95% CI) for a 16ppb increase in the 7-day average daily 1-hour maximum ozone concentration and A) nonperforated or B) perforated appendicitis. Conditional logistic regression estimated the odds of appendicitis in association with a 16 ppb increase in the daily maximum ozone concentration adjusted for mean temperature and relative humidity.
